Triggering a Cell Shape Change by Exploiting Preexisting Actomyosin Contractions

Minna Roh-Johnson,1,4 Gidi Shemer,1,4 Christopher D. Higgins,1 Joseph H. McClellan,1 Adam D. Werts,1 U. Serdar Tulu,2 Liang Gao,3 Eric Betzig,3 Daniel P. Kiehart,2 Bob Goldstein1†

Apical constriction changes cell shapes, driving critical morphogenetic events, including gastrulation in diverse organisms and neural tube closure in vertebrates. Apical constriction is thought to be triggered by contraction of apical actomyosin networks. We found that apical actomyosin contractions began before cell shape changes in both Caenorhabditis elegans and Drosophila. In C. elegans, actomyosin networks were initially dynamic, contracting and generating cortical tension without substantial shrinking of apical surfaces. Apical cell-cell contact zones and actomyosin only later moved increasingly in concert, with no detectable change in actomyosin dynamics or cortical tension. Thus, apical constriction appears to be triggered not by a change in cortical tension, but by dynamic linking of apical cell-cell contact zones to an already contractile apical cortex.

During development, dramatic rearrangements of cells and epithelia play key roles in shaping animals (1–4). Many rearrangements are driven by apical constriction, including neural tube closure (4), failure of which is a common human birth defect (5). Apical constriction is generally driven by contraction of apical actomyosin networks (4). However, it is not well understood how the stresses and tensions generated by actomyosin networks produce cell shape changes in developing organisms (6).

To address this issue, we examined cortical actomyosin dynamics during Caenorhabditis elegans gastrulation. In C. elegans, two endodermal precursor cells (Ea and Ep) internalize through apical constriction (7–9). Transgenic green fluorescent protein (GFP) myosin II–containing particles formed in each cell’s apical cortex, enriched in Ea/p similarly to endogenous myosin (9). The ability to resolve large numbers of particles made it possible to track the detailed dynamics of actomyosin contraction.

**Fig. 1.** Actomyosin contraction precedes the rapid shrinking of the apical surface. (A) Diagram of imaging method. (B) NM2-2::GFP coalescence (white arrowheads) in apical cortex of Ea/p cell. (C) Shrinking of apical surfaces during gastrulation (projections of 10 1-μm z planes, with Ea/p false-colored). (D) Ea/p cell apical surface areas over 575 or 825 s (five embryos each) before closure of the apical surface. (Inset) Apical cell–cell contact zones (arrowheads) on Ep (asterisk). (E) Average radius of apical surfaces derived from area measurements. (F) Mean and 95% CI of radius and myosin particle rate over time. (Inset) Myosin directionality (net distance over total distance, vertical scale 0 to 1) over time (time scale: same as larger graph). (G) Movements of individual myosin particles (arrowheads) near contact zones (white dotted lines) in early or late stages of closure. Arrows at bottom indicate relative distances traveled by each. (H) PIV, three magnifications. Boxes indicate enlarged areas. Left to right are whole embryo at plane of Ea/p apical cortex, Ea/p cells (outlined by dotted line), and part of Ea at border with another cell. (I) Slipping rate calculated from individual particles and contact zones ($P < 0.001$, Student’s t test).
tomyosin networks (Fig. 1A, fig. S1, and movie S1). Neighboring myosin particles moved short distances toward each other into multiple coalescence points, with most particles moving centripetally (toward the center of the apical cell surface) and with new particles forming near apical cell boundaries (Fig. 1B and fig. S2). These particles appear to be components of contracting actomyosin networks because F-actin coalesced similarly (fig. S2) and myosin particles near the center of each coalescence moved at a slower speed than did those further away (fig. S3), as seen in other contracting actomyosin networks (10). Particle tracking and fluorescence recovery after photobleaching (FRAP) experiments suggested that the networks were continuously remodeled by exchange of myosin molecules on and off particles, as expected (fig. S3).

To investigate how apical actomyosin networks shrink apical cell surfaces, we tracked the outlines of these surfaces, the apical cell-cell contact zones, quantitatively (Fig. 1, C and D). Apical areas shrunk gradually or not at all first (Fig. 1, E to G) (11) and then accelerated. We predicted that actomyosin contraction would also begin gradually and accelerate in concert with the contact zones (Fig. 1E). Instead, myosin particles moved centripetally quite rapidly throughout this period [3.19 ± 0.14 μm/min, mean ± 95% confidence interval (CI)] (Fig. 1F), at first with little or no accompanying contact zone movement. Myosin particles near contact zones at first streamed away from the contact zones, which were in many

Fig. 2. Periodic actomyosin coalescence occurs before apical cell profiles shrink in Drosophila gastrulation. (A) Drosophila ventral furrow formation. Circles mark apical myosin enrichment seen before apical cell profiles began to shrink. (B) Kymograph of a cell (diagrammed) showing myosin (green) movement toward a stationary cell-cell boundary (red) before apical shrinking began. (C) Myosin coalesced (green arrowheads) and dissipated (gray arrowheads) before apical cell profiles began to shrink. This is shown quantitatively from one cell in (D) and from 11 cells chosen at random in (E). Heatmaps in (E) show local maxima of apical myosin levels (three-timepoint running averages of myosin level at each timepoint minus the average of 10 timepoints before and after, normalized to maximum and minimum). Green and gray arrowheads mark one case as in (C). Cell 3 is a rare example in which peaks were not seen before apical shrinking began. (F) Slipping rate, defined as in Fig. 1I, early (before apical shrinking, n = 33 myosin particles within 1 μm from centroid, six embryos) and late (during apical shrinking, n = 27 cells, 3 embryos), P < 0.01 (Student’s t test).

Fig. 3. Cortical tension associated with apical constriction is established early and changes little as apical shrinking accelerates in C. elegans. (A) A spontaneous failure, with three timepoints overlain in three colors. (Inset) Entire Ea/p cell apical cortex outlined with enlarged region indicated. Arrows mark individual myosin particles springing apart. (B) Similar data from Ea/p cortical laser cuts done in early or late stages by means of PIV as in Fig. 1H. (C) Initial recoil speeds of myosin particles after spontaneous failures at early (n = 13 myosin particles within 1 μm of center of recoil, six embryos) and late (20 particles, seven embryos) stages, or after laser cuts (48 particles within 4 μm of cut site, seven embryos per stage). Exponential decay T1/2 was 2.20 s in early stages, n = 12 particles; 2.38 s in late stages, n = 20 particles. (D) Working model of forces acting on contact zones (red) and within Ea/p apical actomyosin networks (green, with multiple, interconnected network elements represented as two elements here for simplicity). Results suggest that cortical tension (T) and network stiffness or viscous drag (green dashpots) within Ea/p change little from early to late stages.
cases almost stationary, suggesting that the actomyosin network and contact zones were only weakly mechanically connected at this stage (we refer to actomyosin contractions without contact zone movement as uncoupled movements) (Fig. 1G and movies S2 and S3). Later, contact zones appeared to move almost in unison with many of the myosin particles (referred to as coupled movements) (Fig. 1G and movie S4), suggesting that the myosin and contact zones may have become mechanically connected. Contact zones were never seen to overtake myosin particles in the Ea/p cortex (movies S2 to S5), suggesting that neighboring cells were not simply migrating over Ea/p cells.

Our observations were not entirely consistent with a simple pattern of uncoupled movements early and coupled movements later (fig. S4); instead, some variation existed at each stage. Tracking movements by means of particle image velocimetry (PIV) demonstrated that in general, the myosin particles and contact zones moved increasingly in unison as time progressed (Fig. 1H). We confirmed this result by measuring the rates of individually tracked myosin particles and nearby contact zones, defining the difference between these two rates as a slipping rate (Fig. 1I). Actomyosin contractions appeared to drive contact zone movements with ~25% efficiency in early stages, increasing to ~81% efficiency near the end of Ea/p internalization, based on comparison of measurements from cells with a computer simulation (fig. S5 and movie S6). Labeling cell surfaces with quantum dots or a plasma membrane marker demonstrated that cell surfaces moved in concert with underlying actomyosin network contractions—there may be strong frictional force or drag force between the actomyosin network and the overlying plasma membrane (fig. S6). Thus, slipping between actomyosin and membrane occurred specifically at apical cell contact zones, and the relationship between cytoskeletal dynamics and cell shape change during apical constriction is more dynamic than existing models (3, 4) predict.

To determine whether the phenomenon we found is conserved in other systems, we examined Drosophila ventral furrow cells (11), in which periodic actomyosin contractions cause apical cross-sectional profiles to shrink in pulses (12). We noticed myosin accumulations in some cells even before shrinking of apical profiles began (2A). Myosin coalesced and moved either toward or away from stationary membranes and thus was not well connected to contact zone movements at first (Fig. 2B and movie S7). One or more rounds of myosin enrichment and disipation occurred in most cells (89%; n = 55 cells) before apical profiles began to shrink (Fig. 2, C to E). These early actomyosin contractions occurred periodically, with a time interval of 75 ± 24 s, which is similar to that previously measured just after this stage, during apical constriction (12). Some of the early contractions might contribute to cell surface flattening in Drosophila because apical surfaces are not yet completely flattened at this stage (13), although many early contractions were not centripetally directed (Fig. 2B). Myosin moved at a faster rate than did nearby contact zones at first, and this difference was significantly reduced later, as also observed in C. elegans (Fig. 2F). Thus, the early activation of actomyosin contraction, before apical cell profiles begin to shrink, might be a conserved feature of apical constriction.

We hypothesized that a change in the apparent efficiency of actomyosin-contact zone connections suggested by our C. elegans results might be a secondary effect of changes in viscoelastic properties—for example, stiffening or softening of actomyosin networks in contracting cells or their neighbors. We tested this in two ways. First, we analyzed a naturally occurring phenomenon. The apical networks in Ea/p cells occasionally failed spontaneously, with centripetally moving myosin particles suddenly springing away from one another (Fig. 3A). During recoil, myosin particle movements slowed exponentially, suggesting that the apical cortex behaves as a viscoelastic network (14–16), and initial recoil speeds and their exponential decays were similar between early and late stages, suggesting little change in cortical tension or stiffness of the network over time (Fig. 3B). Second, we cut the cortical actomyosin network using a focused ultraviolet laser beam and measured initial recoil speed as a quantitative estimate of tension in the network (18–23). The cortical network recoiled rapidly from cuts in Ea/p (Fig. 3, B and C), again with little change in initial recoil speed between early and late stages (Fig. 3B). Cutting a neighboring cell’s cortex produced a recoil that also did not change significantly over time, and that was slower than in Ea/p (Fig. 3B), suggesting that network tension is lower in this cell. Thus, the large difference in the degree of coupled movement between early and late stages is accompanied by little measurable difference in the viscoelastic properties of cortical networks.

These results reveal that the cortical tension associated with apical constriction (Fig. 3D) is established well before apical constriction begins and suggest that the differences between early and late stages might be explained by a change in efficiency of actomyosin-contact zone connections alone.

These results support a picture in which a continuously coalescing actomyosin network adds little cortical tension as it begins to move apical cell-contact zones; the tension involved in coalescing the apical actomyosin network is great compared with the small additional tension required to pull contact zones. Although this model may appear counterintuitive, it is in fact consistent with estimates of forces in other biological systems on this size scale (19, 24).

Our results build a model of apical constriction in which the relevant cytoskeletal dynamics can run constitutively, transitioning to driving rapid cell shape change at a later time. We speculate that there may exist in this system a molecular clutch—a regulatable, molecular connection between actomyosin networks and contact zones, transmitting the forces generated by actomyosin contraction to the contact zones. Molecular clutches coordinate actin dynamics and adhe-

**Fig. 4.** Targeting classical cadherin and Rac signaling prevents coupled movements but not actomyosin contraction. (A) Closure speed (micrometer-per-minute decrease in average diameter) of apical cell areas in hmr-1(RNAi) or ced-5(n1812) does not reach the speed found in wild-type embryos (P < 0.05). (B and C) PIV in hmr-1(RNAi);ced-5(n1812) doubles. Myosin moves centripetally with little membrane movement in the same direction at either stage. This is shown for individual particles in (D), with quantification as in Fig. 1I in (E). Black dotted lines on hmr-1 bars in (E) mark wild type for comparison. ***P < 0.001 (Student’s t test).
Nucleosomes Suppress Spontaneous Mutations Base-Specifically in Eukaryotes

Xiaoshu Chen,1,2 Zhidong Chen,1 Han Chen,1 Zhijian Su,3,4 Jianfeng Yang,1 Fangqin Lin,1 Suhua Shi,1 Xionglei He1,2*

It is unknown how the composition and structure of DNA within the cell affect spontaneous mutations. Theory suggests that in eukaryotic genomes, nucleosomal DNA undergoes fewer C→T mutations because of suppressed cytosine hydrolytic deamination relative to nucleosome-depleted DNA. Comparative genomic analyses and a mutation accumulation experiment showed that nucleosome occupancy nearly eliminated cytosine deamination, resulting in an ~50% decrease of the C→T mutation rate in nucleosomal DNA. Furthermore, the rates of G→T and A→T mutations were also about twofold suppressed by nucleosomes. On the basis of these results, we conclude that nucleosome-dependent mutation spectra affect eukaryotic genome structure and evolution and may have implications for understanding the origin of mutations in cancers and in induced pluripotent stem cells.

The mutation rates and spectra of adenine, thymine, cytosine, and guanine vary among the four bases that constitute DNA (1–3). In particular, cytosine is subject to a high rate of hydrolytic deamination, which is a major source of C→T mutations (4). DNA melting is a rate-limiting step for cytosine hydrolytic deamination, because only when DNA is in its single-stranded form are both the N-3 and C-4 positions of the cytosine base subject to chemical changes mediated by water (5). Due to ambient thermal fluctuations, a DNA double helix can spontaneously denature in local regions under normal physiological conditions within a cell, producing transient single-stranded DNA bubbles (6), a phenomenon called “DNA breathing.” Most eukaryotic genomic DNA is packed into nucleosomes, structural units of chromatin composed of ~147 base pairs (bp) of DNA wrapped around a histone octamer and containing ~10 nucleosomes per 40 bp of DNA. The packing of DNA into nucleosomes has been found to affect the accessibility of DNA to repair enzymes (7, 8) and to affect the expression of genes (9).
