Edited by M. Sternberg

Gβ subunits from heterotrimeric G-proteins (guanine nucleotide-binding proteins) directly bind diverse proteins, including effectors and regulators, to modulate a wide array of signaling cascades. These numerous interactions constrained the evolution of the molecular surface of Gβ. Although mammals contain five Gβ genes comprising two classes (Gβ1-like and Gβ5-like), plants and fungi have a single ortholog, and organisms such as *Caenorhabditis elegans* and *Drosophila melanogaster* contain one copy from each class. A limited number of crystal structures of complexes containing Gβ subunits and complementary biochemical data highlight specific sites within Gβs needed for protein interactions. It is difficult to determine from these interaction sites what, if any, additional regions of the Gβ molecular surface comprise interaction interfaces essential to Gβ's role as a nexus in numerous signaling cascades. We used a comparative evolutionary approach to identify five known and eight previously unknown putative interfaces on the surface of Gβ. We show that one such novel interface occurs between Gβ and phospholipase C β2 (PLC-β2), a mammalian Gβ interacting protein. Substitutions of residues within this Gβ–PLC-β2 interface reduce the activation of PLC-β2 by Gβ1, confirming that our *de novo* comparative evolutionary approach predicts previously unknown Gβ–protein interfaces. Similarly, we hypothesize that the seven remaining untested novel regions contribute to putative interfaces for other Gβ interacting proteins. Finally, this comparative evolutionary approach is suitable for application to any protein involved in a significant number of protein–protein interactions.

Keywords: heterotrimeric G-proteins; phospholipase C-β2; protein surface evolution; interface prediction; PLC-β2–Gβγ interaction interface

Abbreviations used: G-protein, guanine nucleotide-binding protein; GRK, G-protein-coupled receptor kinase; MSA, multiple sequence alignment; PLC-β2, phospholipase C β2; RGS9, regulator of G-protein signaling 9; ROI, region of interest; RSA, relative solvent accessibility.

Introduction

Gene duplication is a fundamental source of genetic and phenotypic novelty.[1] After duplication, one of the new paralogs is freed from functional constraint, enabling it to evolve new functions. For genes encoding proteins that interact with other proteins, this process often liberates one copy to develop a new set of interactions. This is particularly true for signaling molecules that are used by organisms to communicate between cells and to perceive their environment. For example, evolution of increasingly complex organisms correlates with the enormous diversification of heterotrimeric G-protein (guanine nucleotide-binding protein) signaling complexes and cell surface G-protein-coupled receptors. The G-protein complex consists of a heterotrimer composed of Gα, Gβ, and Gγ subunits. Upon activation by cell surface receptors, the complex dissociates into a free Gα subunit and a Gβγ dimer, both of which bind to and signal through other proteins. Signaling typically terminates when the heterotrimer reforms.[2,3] *Saccharomyces cerevisiae* has two Gα genes but only one each of Gβ and Gγ genes; mammalian genomes encode 16 Gα, 5 Gβ, and 12 Gγ genes.[2] This complex array of subunit combinations allows for diverse signaling possibilities. It was previously thought that Gα was the primary signaling molecule in mammals, while the sole function of Gβ was to inhibit Gα signaling and to provide for its membrane localization.[4] It is now clear that Gβ also modulates downstream targets; a subset of signaling pathways is uniquely regulated by the Gβ subunit.[5]

Several proteins that bind Gβ have been identified in mammals. In addition to Gα and Gγ, interacting proteins such as the localization chaperone phosducin, G-protein-coupled receptor kinases (GRKs), phospholipase C β2 (PLC-β2), regulator of G-protein signaling 9 (RGS9), calcium channels, potassium channels, and adenylyl cyclase 2 bind Gβ proteins. Mammalian Gβ interacting proteins arose differentially over evolutionary time as not all eukaryotes contain homologs to all known interactors.[2] For example, Gα and phosducin are present in all eukaryotes beginning with plants. Canonical RGS9, PLC-β2, and GRK2 originated and were maintained in metazoans at least by the time of the formation of annelids since *Caenorhabditis elegans* contains bona fide RGS9, PLC-β2, and GRK2 orthologs.[6–8] As the Gβ subunit acquired additional binding partners throughout evolution, new Gβ–protein interfaces likely evolved to accommodate these interactions. These new interfaces may have partially overlapped with existing interfaces since, for example, the interface from many Gβ interactors overlaps with the Gα–Gβ interface.[9] However, these interfaces may have also utilized regions on the Gβ molecular surface that previously had no associated function.

Two major experimental approaches, structural and biochemical studies, have characterized some binding interfaces between Gβ and interacting proteins. Currently, there are four crystal structures of mammalian Gβ subunits in complex with signaling proteins: Gβ1γ1–Gα,[10] Gβ1γ2–GRK2,[11] Gβ1γ1–phosducin,[12] and Gβ5–RGS9.[13] These structures provide a three-dimensional view of where proteins interact but provide limited information regarding the importance of individual contacts. Additionally, structures of Gβ in complex with peptides[14,15] provide partial information on physiologically relevant interfaces within Gβ. Biochemical studies include both targeted mutational studies[9,16,17] and targeted domain-swapping or peptide-binding experiments.[18–20] Mutational studies directed by the structural studies are limited by the number of available structures. Interpretation of these studies is complicated by overlap between the implicated binding regions. When crystal structures of a particular Gβ complex are not available, mutations are frequently targeted to an interface identified in a solved Gβ complex structure. For example, Ford *et al*.[9] created several mutations in the Gα binding interface to show that this interface was utilized in part by five other interacting proteins. This type of approach however does not elucidate binding sites, or even those regions of the binding interface, that are not shared with the Gα interface. To locate these alternative sites, groups such as Panchenko *et al*.[17] performed mutational analyses outside of known binding areas. Although this study identified mutant regions of Gβ with reduced ability to activate PLC-β2, much refinement remains necessary to identify individual critical interaction sites. Moreover, this study left many regions of the Gβ surface unexplored.

Bioinformatic analyses have been developed to identify functional residues, including those composing conserved patches on the surface of a protein that may function as a binding interface. Three such analyses include evolutionary trace,[21] DIVERGE,[22,23] and ConSurf.[24] All three rely on multiple sequence alignments (MSAs) and phylogenetic trees to identify structurally clustered functional residues. Evolutionary trace has been applied to Gβ and the two predicted interfaces correlated with those of Gα and Gγ.[25] To date, none of these three methods has predicted previously uncharacterized Gβ interfaces.

We took advantage of both the rich source of divergent Gβ subunit sequences and the differential evolutionary emergences of known Gβ interactors to understand not only how to predict novel interaction interfaces on the Gβ surface in the absence of crystallized complexes but also how these new interactions gave rise to new binding surfaces. These results can be utilized for more targeted and informed biochemical studies. Based on the hypothesis that the acquisition of mammalian-like sequence identity on the surface of Gβ reflects the utilization of new binding interfaces, we applied a suite of bioinformatic and phylogenetic techniques to follow the shift in patterns of amino acid conservation in Gβs, concentrating on changes between distinct points in the evolutionary history of the Gβ subunit represented by five reference

species. By placing this conservation in a structural context, we predicted regions of interest (ROIs) that are composed of adjacent surface residues that simultaneously evolved to residues conserved with mammals. We identified a novel PLC-β2 interface by demonstrating that at least one ROI that became conserved in *C. elegans* is involved in PLC-β2 activation by Gβ. Similarly, we propose that the remaining ROIs also compose at least portions of binding interfaces.

Results and Discussion

Gβ proteins fall into two major classes: Gβ1-like and Gβ5-like

Since most extant plant and fungal species have a single Gβ, while nematodes and later metazoans have at least two Gβ subunits, the first Gβ gene duplication occurred between the splitting of fungi and *C. elegans* from the mammalian lineage. To compare preduplication plant and fungal Gβ sequences with extant postduplication Gβ sequences from metazoans, we reconstituted ancestral sequences to plants and to fungi from MSAs (Figs. S1 and S2, respectively) of extant plant and fungal Gβ sequences using the Bayesian ancestral reconstruction implemented in MrBayes (see Materials and Methods). These inferred preduplication ancestors were important as they, and not individual plant or fungal species, reflect sequence constraints common to all plants or fungi and therefore more closely reflect the predecessor of all extant postduplication Gβ genes.

An MSA containing Gβ sequences from the plant ancestor, fungal ancestor, and extant *C. elegans*, *Drosophila melanogaster*, and human Gβ sequences was created (Fig. S3) for comparison of preduplication and postduplication Gβ genes. This MSA was used to generate a Bayesian phylogenetic tree (Fig. S4) that elucidates the evolutionary relationship between the different Gβ proteins. Human Gβ1, Gβ2, Gβ3, and Gβ4 sequences formed a monophyletic Gβ1-like clade also containing *D. melanogaster* and *C. elegans* Gβ1 sequences. Human Gβ5 formed a Gβ5-like monophyletic clade containing *D. melanogaster* Gβ5 and *C. elegans* Gβ2 sequences. Both plant and fungal ancestors were outside of these two clades.

Based on the phylogenetic data (Fig. S4) and corroborating previous observations that Gβ5 often behaves differently from the other four mammalian Gβ proteins,[5] metazoan Gβ proteins can be grouped into two major classes, Gβ1-like and Gβ5-like. The initial Gβ gene duplication between fungi and *C. elegans* gave rise to the Gβ5-like family since *C. elegans* is the earliest species examined to contain a Gβ5-like protein. The ancestral plant and fungal Gβ proteins each contains characteristics of both major classes, but neither strictly belongs to either class. Finally, the phylogeny revealed that, after duplication, the Gβ5-like genes diverged from the ancestor more than the Gβ1-like genes, while the Gβ1-like genes maintained more ancestral characteristics.

Interaction interfaces identified from Gβ complex structures co-evolved with interactors

Complexes containing mammalian Gβ1–Gα, Gβ1–GRK2, Gβ1–phosducin, and Gβ5–RGS9 are shown in Fig. 1 (Gβ in spheres and interacting protein in ribbons). While these structures provide a three-dimensional view of Gβ–protein complexes, the interfaces between the proteins must still be defined.[26] To define sites of interaction, we calculated the solvent accessibility of each residue in the four crystal structures using Naccess.[27] Those Gβ residues whose side chains have lower relative solvent accessibility (RSA) by more than 5% between the monomer and the protein complex, including those that hydrogen bond with the binding partner, were defined to comprise the interface and were noted on the structure (see Materials and Methods) (Fig. 1). These four Gβ interacting proteins (1) cover three major areas on the Gβ surface, (2) all partially overlap with one another, and (3) appeared at different times over Gβ evolution.

In order to examine the evolution of these known Gβ–protein interfaces, we compared the patterns of amino acid conservation within these regions. For each interface residue in the MSA, comparisons were made between each of the four reference sequences and the corresponding mammalian residue. For Gβ1 complexes (Gα, GRK2, and phosducin), the plant ancestor, fungal ancestor, *C. elegans* Gβ1, and *D. melanogaster* Gβ1 were compared with bovine Gβ1. Identical interface residues were mapped onto the bovine Gβ1 structure (1got.pdb). For the RGS9 complex, the plant ancestor, fungal ancestor, *C. elegans* Gβ5, and *D. melanogaster* Gβ5 were compared with mouse Gβ5 and identities were noted on the mouse Gβ5 structure (2pbi.pdb). As expected, conservation within known binding areas correlated with the known utilization of these regions (Fig. 2). The complexes subsequently discussed were observed in the four crystal structure complexes.

Gβ1–Gα

The Gβ–Gα interaction is the most ancient; thus, it would be expected that the Gα–Gβ interface is well conserved in all organisms studied. As expected, the Gα binding interface was highly conserved (77%–100% identity) in all sequences analyzed (Fig. 2a, top row) as illustrated by the predominantly orange coloration of the interface.

Gβ1–GRK2

The GRK2 interface (Fig. 2a, second row) was completely conserved in *C. elegans* and *D. melanogaster*, correlating with the emergence of GRK2 between fungi and *C. elegans*. Although a large portion of the interface was also conserved in the

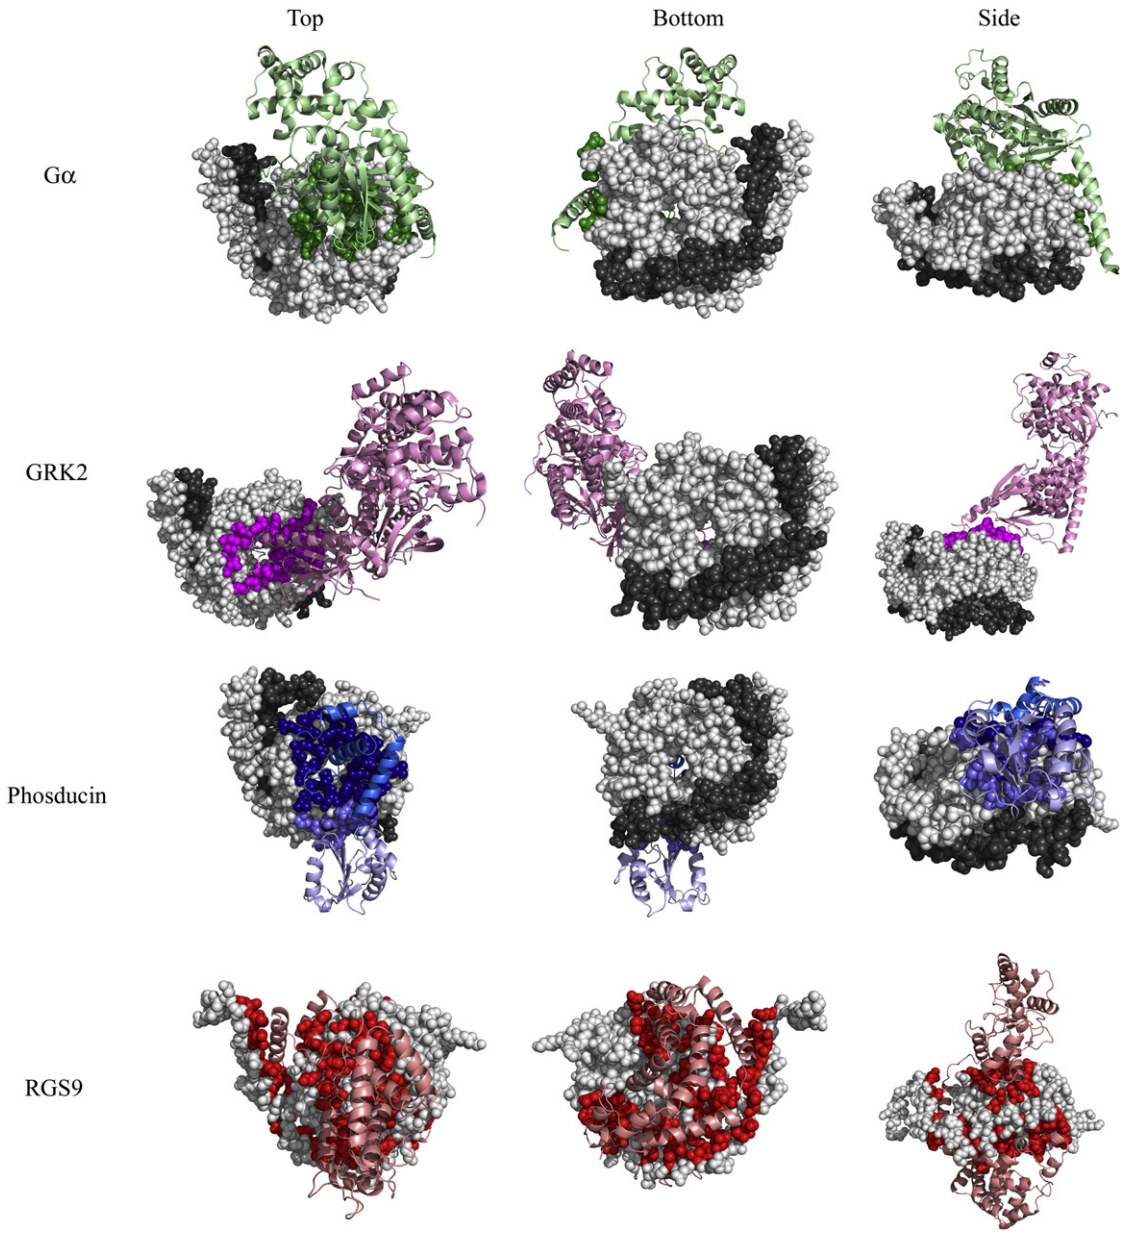

Fig. 1. Binding interfaces of four Gβ interacting proteins as determined by crystal structures. Top, bottom, and side views of Gβ or the Gβγ dimer (Gβ in light gray spheres and Gγ in dark gray spheres) bound to four interacting proteins (ribbon): Gβ1–Gα in green (1got.pdb), Gβ1–GRK2 in magenta (1omw.pdb), Gβ1–phosducin in blue (N-terminal domain is dark and C-terminal domain is light; 1a0r.pdb), and Gβ5–RGS9 in red (2pbi.pdb). Gβ residues that contact each interacting protein are colored accordingly. Binding contacts were determined by evaluating the solvent accessibility difference between single molecules and those in complex.

plant (62%) and fungal (92%) ancestors, this can be attributed to the fact that the interface largely overlaps that of Gα.

Gβ1–phosducin

Plants contain several phosducin-like sequences,[28] and our yeast three-hybrid data suggest that at least one phosducin in *Arabidopsis thaliana* interacts with the *A. thaliana* Gβ (Fig. 3). The phosducin interface is highly conserved in *C. elegans* and *D. melanogaster* (94% identity); however, it is only partly conserved in plant and fungal ancestors (55% and 64%, respectively). Mammalian phosducin has two domains: a helical N-terminal domain and a C-terminal domain (see Fig. 1 for locations of N- and C-terminal binding interfaces), both of which bind mammalian Gβ.[29] The plant and fungal ancestors show high conservation in the N-terminal binding area (68% and 76%, respectively) but not in the C-terminal binding area (25% and 38%, respectively) (Fig. 2a, third and fourth rows). Two possible explanations for these results are that plants and fungi bind only one phosducin domain and not the second and that the second domain binds in a species-specific manner.

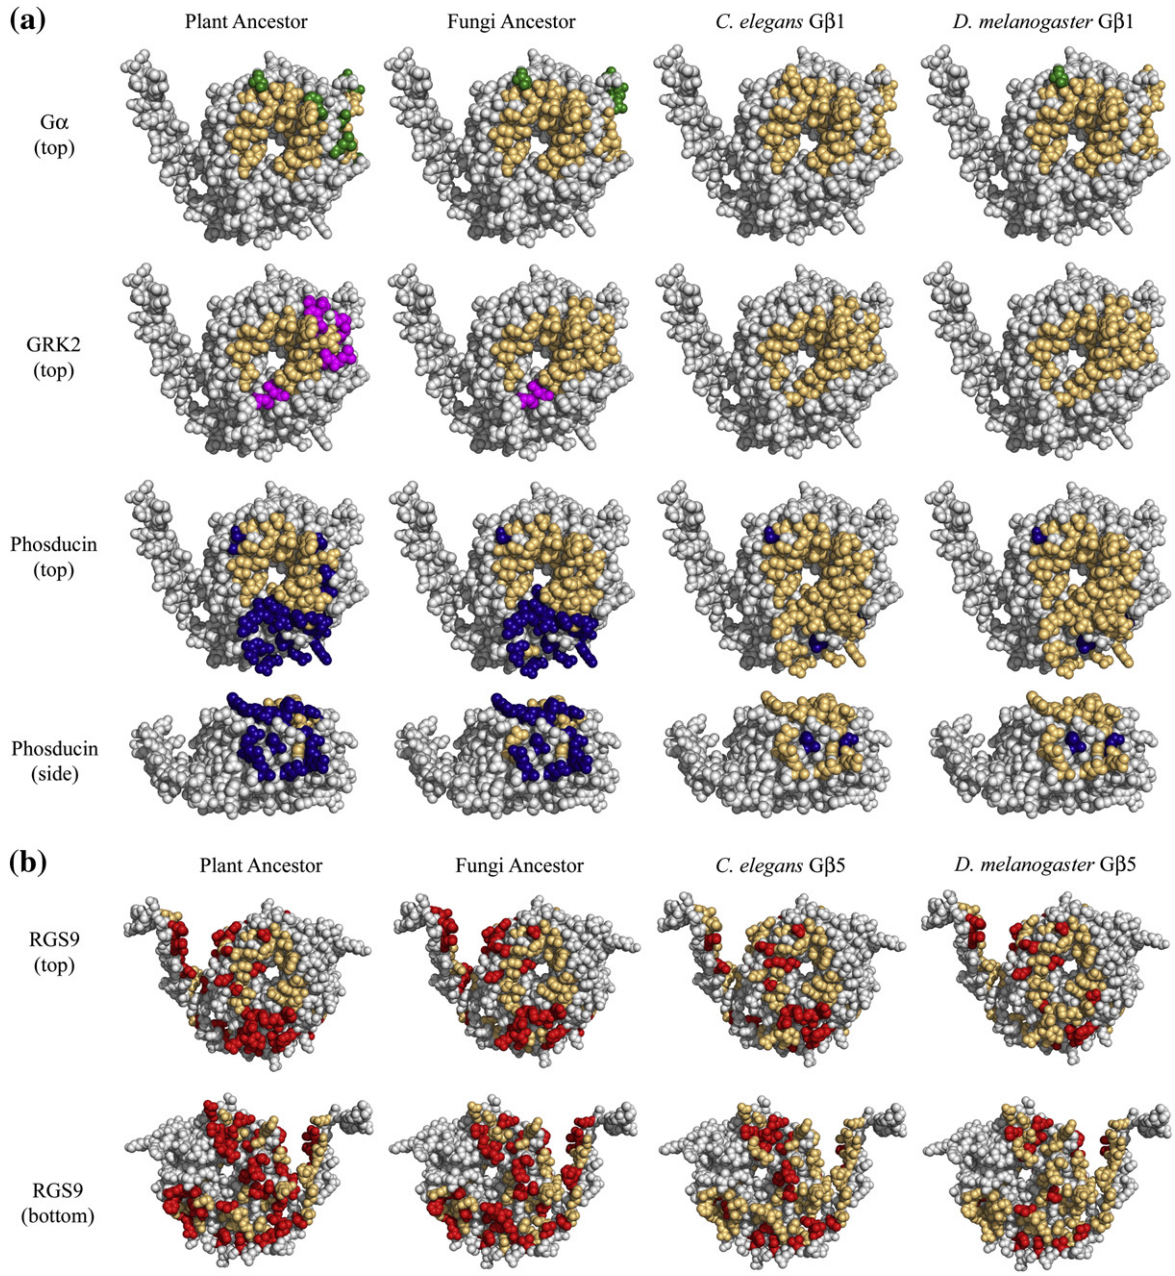

Fig. 2. Conservation within known binding interfaces based on bovine Gβ1 crystal structures. (a and b) Conservation of the (a) Gα, GRK2, and phosducin binding interfaces on Gβ1 (1got.pdb) and (b) RGS9 binding interface on Gβ5 (2pbi.pdb) in four reference organisms. While the interface is composed of all colored residues, conserved residues are colored light orange and nonconserved residues are colored green (Gα), blue (phosducin), magenta (GRK2), or red (RGS9). Only residues in the binding area were analyzed.

Gβ5–RGS9

The RGS9 binding interface (Fig. 2b) is only 42% identical in the plant ancestor and 50% identical in the fungal ancestor. Correlating with the genesis of the RGS9 protein, conservation in the binding area rises to 67% and 76% in *C. elegans* and *D. melanogaster*, respectively. Although this is markedly less than the 90%–100% identity seen in corresponding Gβ1 binding areas, it is important to note the size of the RGS9 interface. Encompassing 103 residues, the RGS9 interface is over three times larger than the Gα (31 residues) and GRK2 (26 residues) interfaces and twice the size of the phosducin interface (47 residues). Thus, we expect that the RGS9 interface could tolerate more substitutions than its smaller counterparts and that only those residues making energetically critical contacts in the interaction interface are conserved.

Newly conserved regions of adjacent surface residues arose over time and likely contribute to Gβ–protein interfaces

As conservation within known Gβ–protein interfaces correlated with the emergence of proteins

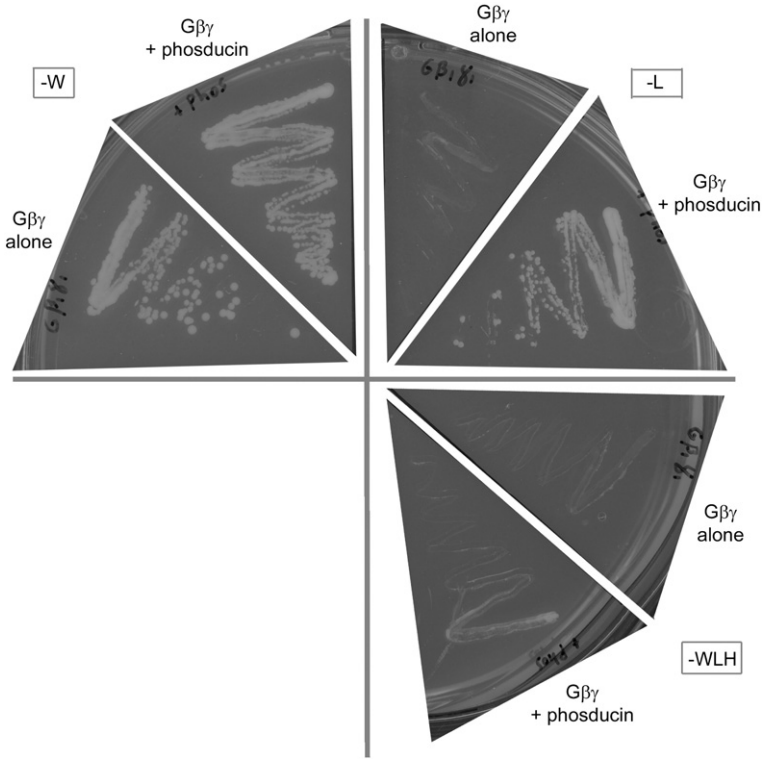

Fig. 3. An *Arabidopsis* phosducin and Gβ interact physically. Growth of yeast strain AH109 containing the genes indicated (AtGβ1γ1 alone or AtGβ1γ1 and phosducin) on yeast dropout medium. Medium missing tryptophan (−W) selects for the AtGβ1γ1 vector, resulting in positive growth for both genotypes. Medium missing leucine (−L) selects for the phosducin vector, resulting in no growth for the strain lacking phosducin and positive growth for the strain containing phosducin. Medium missing tryptophan, leucine, and histidine (−WLH) selects for a positive interaction between the two genes, resulting in no growth for the strain containing AtGβ1γ1 alone and positive growth for the strain containing both AtGβ1γ1 and phosducin. The latter growth indicates that the two genes physically interact.

utilizing these interfaces, we next used a similar method of analysis to predict *novel* binding interfaces. This unbiased comparative evolutionary analysis was not restricted to predetermined binding interfaces and was performed on the entire molecule, but it was otherwise similar to the methods used in the validation stage described in the previous section. Bovine Gβ1 was compared at each residue in the MSA with the plant ancestor, fungal ancestor, *C. elegans* Gβ1, and *D. melanogaster* Gβ1 (Fig. 4a). Identical residues between the plant ancestor and bovine Gβ1 were located on the surface of Gβ1 and colored dark green. These 162 residues form region zero (ROI0) and represent the primordial function of the Gβ molecule, since the plant molecule is the most ancestral-like of the Gβ family. For all other reference species, conserved residues that continued to be conserved from the previous species were colored light green (indicating the persistence of an existing function), while newly conserved residues were colored dark green (indicating the emergence of potential novel function). Similarly, mouse Gβ5 was compared with the plant ancestor, fungal ancestor, *C. elegans* Gβ5, and *D. melanogaster* Gβ5 and conserved residues were mapped onto the structure (Fig. 4b).

Due to its primordial nature, ROI0 contains residues conserved both for structural maintenance and for interaction surfaces. ROI0 contains the residues (e.g., W99, M101 K57, Y59, L117, D186, D228, and W332) previously indicated as interacting with multiple effectors and that also made energetically critical contacts in various interaction interfaces.[9,14] Subsequent non-ancestral ROIs in each organism (for both Gβ1 and Gβ5) were defined as clusters of three or more structurally adjacent (within 5 Å[30]) newly conserved surface residues and are encircled on the structure (Fig. 4; for residue designations, see Table 1). It is important to note that although all surface-exposed residues could form part of an interface, we chose a larger cluster size (containing three or more newly fixed residues) in order to predict clusters that likely make significant energetic contributions to binding. We also ignored several large clusters near the Gγ binding area due to their likely involvement in the Gβ–Gγ interface.

Five of the 13 ROIs (ROI7, ROI10, ROI11, ROI12, and ROI13) could be explained by existing structural data. ROI7 lies in the phosducin binding region on Gβ1 (Fig. 1). Portions of ROI10–ROI13 localize to the RGS9 binding interface on Gβ5 (Fig. 1). Additionally, a portion of ROI2 was shown to interact with Gα, adenylyl cyclase 2, calcium channels, potassium channels, and PLC-β2 in mutational studies.[9] These data support the hypothesis that regions of adjacent surface residues that become conserved to the mammalian state at the same time are likely sites of Gβ–protein interactions. Similarly, we hypothesize that the remaining ROIs are binding interfaces with yet-to-be identified interacting proteins or additional, undescribed binding interfaces with previously identified interacting proteins.

Several ROIs contain Gβ residues that activate PLC-β2

To test our hypothesis that ROIs represent Gβ–protein interaction interfaces, we mutated residues

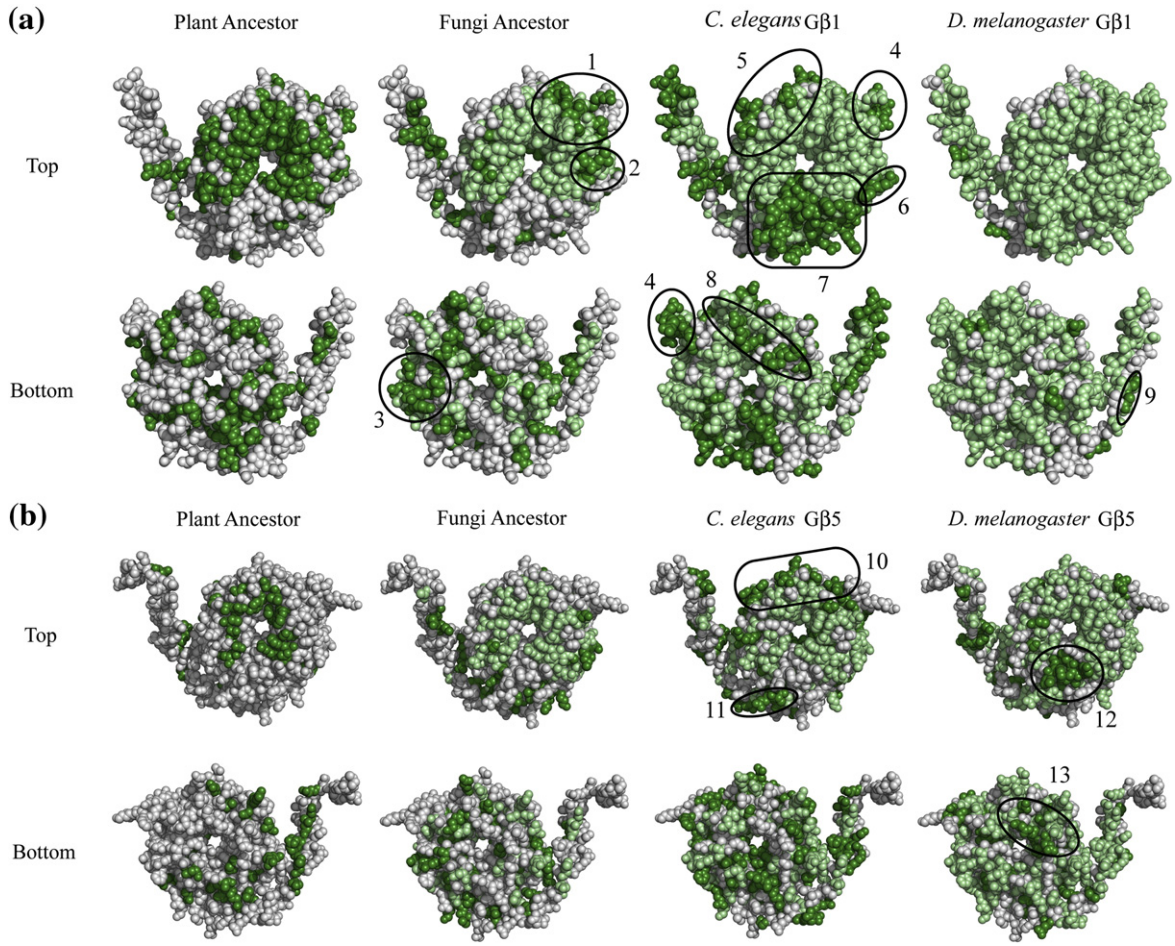

Fig. 4. Gβ ROIs as determined by a comparative evolutionary analysis. Three views (top, bottom, and side) of the evolution of conserved regions in the plant ancestor, fungal ancestor, *C. elegans* Gβ, and *D. melanogaster* Gβ [(a) Gβ1 (1got.pdb) and (b) Gβ5 (2pbi.pdb)]. The dark green regions of the plant ancestor highlight primordial function and form ROI0. In all other organisms, newly conserved residues (those that matched the mammalian value) are colored dark green, while conserved residues present in a previous organism are colored light green. Thus, dark green patches represent acquisition of new function. ROIs are indicated and corresponding residues are listed in Table 1.

likely to interact with PLC-β2. Despite the absence of a crystal structure of the Gβγ–PLC-β2 complex, several studies implicated multiple potential interfaces. Peptide-binding assays implicated a region at the base of Gβ's N-terminal helix.[18,20] A patch of residues near this region was implicated as an interface when it was revealed that the C-terminal tail of Gγ was responsible for the activation of PLC-β2.[19] Therefore, ROI4, ROI6, and ROI7 were chosen for mutational studies due to their proximity to the general region implicated in these peptide-binding and domain-swapping experiments. Additionally, all three regions became conserved between the fungi and *C. elegans* split, corresponding with the emergence of PLC-β proteins.

In order to evaluate the extent of PLC-β2 activation, we transfected COS-7 cells with wild-type and mutant forms of Gβ1 and wild-type Gγ2 in the presence or absence of PLC-β2. Equal expression of all Gβ1, Gγ2, and PLC-β2 constructs was confirmed by immunoblot analysis. Additionally, equivalent expression of Gγ2 was observed in the presence of all forms of Gβ1. The location of each mutation on the surface of Gβ1 is depicted in Fig. 5. The construct containing the double mutation T65A_D322A, which is located outside of the predicted binding region and lacks sequence conservation with bovine Gβ1, activates PLC-β2 to the same extent as wild-type Gβγ. Conversely, two single mutations, W99A and D228A, abolish PLC-β2 activation as previously shown.[9] Within the newly predicted binding areas, the mutations that most significantly reduced PLC-β2 activation were found in ROI4 and ROI6 (Figs. 4a and 5). R52S_F335S slightly reduced PLC-β2 activation, while K127S_R129S_E130S nearly abolished PLC-β2 activation. In summary, when residues within the new binding areas predicted by our *de novo* analysis are mutated, there is a concordant drop in activity; conversely, when residues we identified as not part of binding surfaces are mutated, there is no change in activation. These results indicate that our evolutionary structural analysis predicts the nonoverlapping portions of interaction interfaces and can be used to further dissect the PLC-β2 interface on Gβ1.

Table 1. ROI residue numbers

ROI	Residues	First conserved in
1	R96, S97, S98, I120, R134, E138, E172	Fungi Gβ1
2	L55, A56, S334	Fungi Gβ1

13	N163, L203, P205, E207	*D. melanogaster* Gβ5

Shown are mammalian residue positions for each Gβ residue within the ROIs highlighted in Fig. 4.

Molecular evolution can be used as a tool to predict novel binding interfaces

Conservation is a hallmark of a residue's functional importance,[23] and as the plant ancestor is most similar to the most ancient Gβ molecule, primordial Gβ function can be inferred to correlate with those residues that were conserved in the plant ancestor (ROI0) (Fig. 4). These primordial functional regions comprise both conserved protein-binding interfaces and regions of the protein important for structural integrity. With each comparative step (e.g., between plants and fungi, fungi and *C. elegans*, etc.), new functional regions became conserved. These regions may represent sites of novel Gβ–protein interaction or new interaction sites with existing proteins (co-evolution). Lineage-specific protein interactions will however not be revealed by this type of analysis. Lineage-specific interactions would be indicated by conservation of a residue within a particular organismal group (e.g., within all plants or within all fungi) that is *not* conserved outside of that group (e.g., between plants and fungi). All interfaces identified in our analysis are ones that are maintained in the mammalian lineage. Although species-specific interactions are also of great interest, a different approach would be necessary to reveal those regions.

The Gβ gene family was produced by a series of gene duplications. After these events, the new Gβ paralogs likely evolved novel functions as a result of relaxed functional constraint. Eventually, as these new Gβ functions become critical to the organism, these new functional regions become highly conserved regions of the Gβ structure and include the ROIs we identified. We hypothesize that these ROIs represent regions of newly acquired function in the organism in which they first appeared. For instance, portions of six ROIs presented in Fig. 4 (ROI2, ROI7, and ROI10–ROI13) contain residues that likely bind interactors as previously identified in mutational or structural studies. The remaining ROIs in Fig. 4 are in regions that lie outside of known regions presented thus far. Although interactions with many proteins have been determined by mutational studies, many studies focus on known interfaces and therefore indirectly introduce bias. For example,

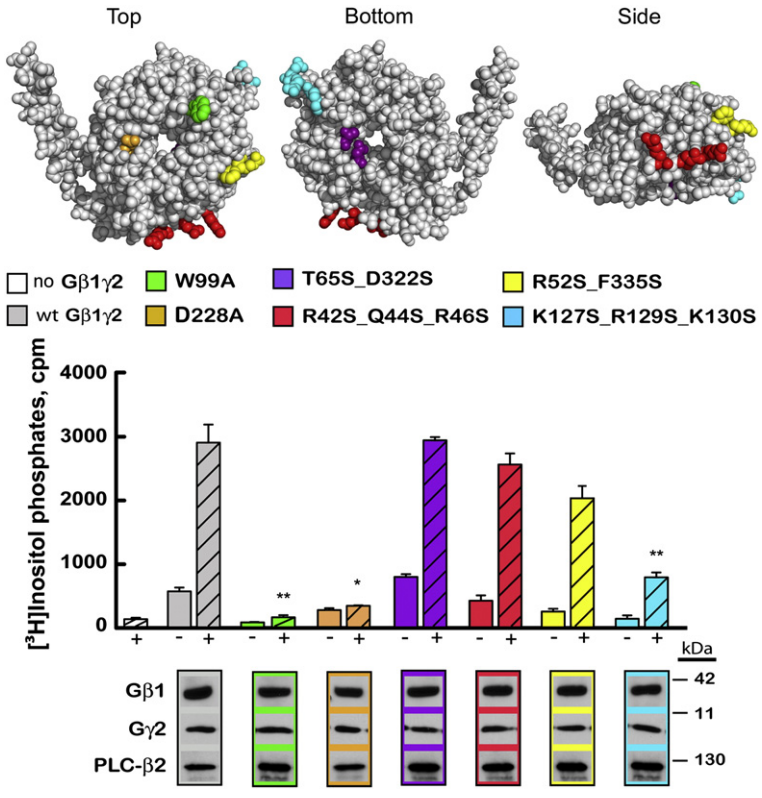

Fig. 5. Regions of Gβ involved in PLC-β2 activation. Groups of residues mutated on the Gβ surface (1got.pdb) are colored and coordinate with colors in the bar graph and associated blots. Wild-type and mutant Gβ1 subunits were tested in the absence (−) or presence (+) of PLC-β2 for their ability to activate PLC-β2 (∗$p<0.01$ and ∗∗$p<0.005$; error bars represent standard error). Immunoblot analysis confirmed equal expression of all proteins utilized.

since the Gα binding area is utilized in many Gβ–protein interactions, studies historically focused on these residues. Our *de novo* analysis eliminates this bias, generating a set of potential binding interfaces that are yet to be explored by mutational studies. As with the residues implicated in the PLC-β2 binding interface, these ROIs would make ideal targets for site-directed mutagenesis. In this manner, we can identify new Gβ interacting proteins and further characterize interactions with existing proteins. Ultimately, this will allow us to characterize new Gβ-mediated signaling pathways.

Materials and Methods

Ancestral reconstruction

To reconstruct plant and fungal ancestors, we queried sequence databases with known plant and mammalian Gβ sequences for full-length plant and fungal Gβ homologs. Additionally, Gβ sequences were also retrieved for two outgroups: Entamoeba (*Entamoeba dispar*) and diatom (*Thalassiosira pseudonana*). MSAs were generated in ClustalX.[31] Expasy and Genbank IDs for each gene used in the alignment are denoted in Figs. S1 and S2. For each MSA generated, all gaps except those found exclusively in the two outgroups were removed. From the resulting NEXUS file, ancestors were generated with MrBayes[32,33] using the fixed equalin model, using the inverse gamma rate, and sampling 100,000 generations at a frequency of 100. In order to eliminate ancestral residue values chosen with low confidence, we accepted and included in the ancestral sequence only those residues predicted >90% of the time with a maximum value >0.8. All other residues were assigned a value of "X" as they were too variable to be called with confidence.

Sequence collection, alignment, and phylogeny generation

All Gβ sequences from *D. melanogaster*, *C. elegans*, and human (Expasy and Genbank sequence IDs are denoted in Fig. S3) were combined with the plant and fungal ancestral sequences and the diatom and Entamoeba outgroups to create an MSA (see previous section for alignment and NEXUS file generation). The alignments were made robust by structural comparisons between bovine Gβ1 and mouse Gβ5. MrBayes[32,33] was run using a fixed equalin model, using the inverse gamma rate, and sampling 1 million generations at a frequency of 100 for three independent runs with a burn-in of 250,000 generations to generate a consensus phylogenetic tree.

Interface determination

In order to identify binding interfaces from structures of Gβ in complex with interacting proteins, we used Naccess[27] to calculate the RSA of all Gβ residue side chains both as a monomer and in complex with other proteins. All residue side chains with an RSA decrease >5% (RSA of Gβ monomer–RSA of complex, >5) between monomer and complex were denoted as being present in the interface. This group of residues also included all Gβ residues that formed hydrogen bonds with the interacting protein as determined in the PyMOL molecular modeling system.[34] The 5% ΔRSA value was chosen because it is more stringent than the commonly utilized 1-Å^2 change in absolute solvent accessibility[26,35] but still included all residues that form hydrogen bonds. Additionally, a residue with ≥5% RSA is often designated as a surface residue, while a residue with <5% RSA is designated as an interior residue.[26,35]

Yeast three-hybrid protein interaction

A. thaliana Gβ (AGB1) and Gγ1 (AGG1) were cloned into the pBridge vector (Clontech, Palo Alto, CA). *A. thaliana* phosducin (At5g14240) was cloned into the p-ENTR/D-TOPO vector (Invitrogen, Carlsbad, CA) and then recombined into the pACTGW-attR Gateway vector,[36] which contains an activation domain and is compatible with the pBridge vector. The prey (phosducin) was transformed into yeast strain AH109, which had previously been transformed with the bait (AGB1/AGG1). Both strains (containing the bait alone and containing both bait and prey) were grown on nutritionally selective media. Presence of the bait and that of the prey were confirmed by the expression of nutritional markers (positive growth on media lacking tryptophan and leucine, respectively). Interaction was confirmed by the expression of an additional nutritional marker (positive growth on medium lacking histidine).

Transfection of COS-7 cells with Gβ1, Gγ2, and PLC-β2

The accumulation of [^{3}H]inositol phosphates was measured in transiently transfected COS-7 cells as previously described.[37] Briefly, COS-7 cells were plated in 12-well dishes at a cell density of 60,000 cells per well in Dulbecco's modified Eagle's medium supplemented with 10% fetal bovine serum, 10 U/ml of penicillin, and 10 U/ml of streptomycin. Following incubation for 24 h at 37 °C in an atmosphere of 95% air/5% CO_2, cells were transfected with 200 or 300 ng each of the indicated human Gβ1 and Gγ2 DNA in the presence and in the absence of 30 ng of PLC-β2 and empty vector, for a total of 700 ng of DNA per well. DNA was complexed with FuGENE 6 (Roche Applied Sciences, Indianapolis, IN) as per the manufacturer's protocol prior to transfection. Twenty-four hours posttransfection, the medium was aspirated and cells were metabolically labeled with 1 μCi/well of *myo*-[2-^{3}H(N)]inositol (American Radiolabeled Chemicals, St. Louis, MO) in inositol-free Dulbecco's modified Eagle's medium for 12–16 h. Subsequently, 10 mM LiCl was added. One hour after incubation with LiCl, reactions were stopped by aspiration of the medium and addition of 50 mM formic acid. Samples were neutralized by the addition of 150 mM NH_4OH, and [^{3}H]inositol phosphates were quantified by Dowex chromatography. Statistical significance for comparisons between the activation of PLC-β2 by wild-type Gβ1γ2 and that by each mutant Gβγ was determined by performing Student's *t* test assuming equal variance between the log-transformed number of [^{3}H]inositol phosphates for each construct. Western blotting was performed to confirm equal expression of each construct in COS-7 cells using an antibody directed toward the c-Myc epitope (Invitrogen) on human Gβ1, the hemagglutinin epitope (Roche Applied Sciences) on Gγ2, and a monoclonal antibody (Santa Cruz Laboratories, Santa Cruz, CA) against PLC-β2.
